Does the optical module light up as soon as it receives light

Overview

There have been multiple variants of the electrical interface of optical modules that have been used over the years. The earliest forms of optical modules had an analog NRZ electrical interface. In the transmit direction, the optical module would directly drive the laser or LED with the analog signal coming from the front system card.

Key Takeaways

An optical module does not light up simply because it receives light; it emits light only when driven by an electrical signal.

Optical modules consist of a transmitter and a receiver. The transmitter, typically a laser diode (LD) or light-emitting diode (LED), converts electrical signals into modulated optical signals for transmission through fiber optics . The receiver contains a photodetector, such as a PIN diode or avalanche photodiode, which converts incoming optical signals back into electrical signals . The key point is that the light emission from the module's transmitter is controlled by the input electrical signal, not by the presence of external light. The photodetector in the receiver can detect incoming light, but it does not cause the transmitter to emit light in response. In other words, receiving light does not automatically trigger the module to light up; the module only emits light when it is actively transmitting data . Additionally, optical modules include circuits like automatic power control (APC) to maintain consistent output power, and the extinction ratio measures the difference between light emitted for logical “1” and “0” signals, further emphasizing that light emission is signal-dependent . Direct exposure to strong external light can saturate the photodetector, potentially causing errors, but it still does not make the module emit light . In summary, an optical module's light source is independent of incoming light; it only lights up when electrical signals drive the transmitter.
